The layered honeycomb magnet $\alpha$-RuCl$_3$ has been proposed as a candidate to realize a Kitaev spin model with strongly frustrated, bond-dependent, anisotropic interactions between spin-orbit entangled $\vec{J}_{EF} = \frac{1}{2}$ Ru$^{3+}$ magnetic moments. Here, we report a detailed study of the three-dimensional crystal structure using x-ray diffraction on unwinned crystals combined with structural relaxation calculations. We consider several models for the stacking of honeycomb layers and find evidence for a parent crystal structure with a monoclinic unit cell corresponding to a stacking of layers with a unidirectional in-plane offset, with occasional in-plane sliding stacking faults, in contrast with the currently assumed trigonal three-layer stacking periodicity. We report electronic band-structure calculations for the monoclinic structure, which find support for the applicability of the $\vec{J}_{EF} = \frac{1}{2}$ picture once spin-orbit coupling and electron correlations are included. Of the three nearest-neighbor Ru-Ru bonds that comprise the honeycomb lattice, the monoclinic structure makes the bond parallel to the $b$ axis nonequivalent to the other two, and we propose that the resulting differences in the magnitude of the anisotropic exchange along these bonds could provide a natural mechanism to explain the previously reported spin gap in powder inelastic neutron scattering measurements, in contrast to spin models based on the three-fold symmetric trigonal structure, which predict a gapless spectrum within linear spin wave theory. Our susceptibility measurements on both powders and stacked crystals, as well as magnetic neutron powder diffraction, show a single magnetic transition upon cooling below $T_N \approx 13$ K. The analysis of our neutron powder diffraction data provides evidence for zigzag magnetic order in the honeycomb layers with an antiferromagnetic stacking between layers. Magnetization measurements on stacked single crystals in pulsed field up to 60 T show a single transition around 8 T for in-plane fields followed by a gradual, asymptotic approach to magnetization saturation, as characteristic of strongly anisotropic exchange interactions.

I. INTRODUCTION

There has been considerable recent interest in materials that realize strongly anisotropic, bond-dependent interactions as the resulting frustration effects could potentially stabilize novel forms of cooperative magnetic order or a spin liquid state [1]. A canonical Hamiltonian is the Kitaev spin model on the honeycomb lattice [2], where each bond carries an Ising interaction, but where the Ising axes are reciprocally orthogonal for the three bonds meeting at each lattice site, leading to an exotic quantum spin liquid state with fractional spin excitations. In a pioneering set of papers [3,4] it was proposed that Kitaev physics may be realized in $A_2$IrO$_3$ ($A = $ Na, Li) materials with a tricoordinated, edge-sharing bonding geometry of IrO$_6$ octahedra. Here, the combined effect of strong spin-orbit coupling at the $\text{Ir}^{4+} 5d^5$ site and near-cubic crystal field of the $\text{O}_6$ octahedra stabilize $\vec{J}_{EF} = \frac{1}{2}$ Ir moments, and superexchange via two near $90^\circ$ Ir-O-Ir paths is predicted to couple (to leading order) only the magnetic moment components normal to the plane of the Ir-O-Ir bond, with three such near-orthogonal planes meeting at each Ir site.

Evidence for dominant Kitaev interactions in such materials has been observed in the structural polytypes $\beta$- and $\gamma$-$\text{Li}_2\text{IrO}_3$ where the Ir ions have the same local threefold coordination as in the planar honeycomb, but now form fully connected three-dimensional networks, so-called hyperhoneycomb and stripyhoneycomb, respectively. In both structural polytypes, complex counter-rotating and noncoplanar incommensurate magnetic orders have been observed [5,6], which cannot be reproduced by isotropic (Heisenberg) exchange, but require the presence of dominant ferromagnetic Kitaev interactions [7–9] supplemented by additional smaller interactions. In contrast, the layered honeycomb iridate Na$_2$IrO$_3$ shows a very different magnetic order, with spins arranged in zigzag ferromagnetic chains aligned antiferromagnetically [10–12], believed to be stabilized by the competition between many interactions including a strong ferromagnetic Kitaev term and further neighbor interactions [13]. In Na$_2$IrO$_3$, evidence for the presence of strong Kitaev interactions has been provided by measurements of the diffuse scattering at temperatures above the magnetic ordering transition temperature, which observed a locking of the polarization of spin fluctuations with the wave-vector direction [14]. $\alpha$-RuCl$_3$ has been proposed [15] as a candidate Kitaev material in a $4d$ analog of the layered honeycomb iridates.
This might be surprising at first as the spin-orbit coupling is expected to be considerably weaker in Ru compared to Ir (due to the smaller atomic number), but it was argued [15,16] that (i) the crystal field of the Cl6 octahedra may potentially be much closer to cubic in â-RuCl3 as layers are only very weakly bonded (by van der Waals interactions), in contrast to Na2IrO3 where the O6 octahedra are strongly trigonally squashed due to the strong bonding to the adjacent hexagonal Na+ layers, and (ii) correlation effects in a narrow band could potentially enhance the effects of spin-orbit coupling.

The magnetic properties of â-RuCl3 are currently the subject of much experimental and theoretical investigation [15,17–23]. Early studies have established the existence of two distinct structural polytypes: the â polytype with edge-sharing RuCl6 octahedra forming stacked honeycomb layers with magnetic field below ð14 K (Ref. [24]), and the ß polytype with face-sharing RuCl6 octahedra arranged in chains, which shows no magnetic ordering down to the lowest temperatures measured [25]. However, detailed studies of the three-dimensional crystal structure of the layered (â) polytype have proved difficult because of the prevalence of diffuse scattering due to stacking faults [26], an inevitable consequence of the weak bonding between adjacent honeycomb layers. A trigonal space group P 312 with a three-layer stacking periodicity is usually presupposed based on an early structural study [27], although this structural model has been questioned by later studies [28–30]. In particular, Ref. [29] reported a monoclinic C/2/m stacking of honeycomb layers for the related halide IrBr3 (AlCl3 structure type [31]) and proposed, by analogy, a similar structural framework for â-RuCl3, but no lattice parameters or any other structural details were provided. The difficulty in reliably solving the crystal structure stems from the fact that in principle several candidate stacking sequences of the honeycomb layers may be possible [monoclinic, trigonal, rhombohedral (to be discussed later)] and it is experimentally rather challenging to reliably distinguish between them in the presence of stacking faults and/or when samples may contain multiple twins. Having a reliable determination of the full three-dimensional crystal structure is important for understanding the underlying electronic and magnetic properties, as electron hopping terms, and consequently magnetic interactions and anisotropies, appear to be quite sensitive to the stacking sequence of layers and to weak distortions inside each layer, as we will show later in Sec. V.

Previous studies on single crystals of â-RuCl3 have observed two anomalies near 8 and 14 K in both magnetic susceptibility and heat capacity [17,19,20] (with the transition near 8 K attributed [17] to the onset of zigzag magnetic order as in Na2IrO3), whereas studies on powder samples showed only one anomaly near T N ≳ 13 K (Refs. [24,25]), raising the question of why the powders and single crystals show distinct behaviors. To date, the ground-state magnetic structure is yet to be reported for samples that exhibit a single magnetic phase transition upon lowering temperature.

Here, we report comprehensive results and an extensive discussion of x-ray diffraction measurements on unwinned crystals of â-RuCl3 that display a single magnetic phase transition upon cooling to low temperatures, in agreement with powder samples. We find that the crystal structure is monoclinic, with space group C/2/m. Features in the diffraction pattern necessitated by the assumed trigonal P 312 model are clearly absent. The monoclinic structure of â-RuCl3 is found to be iso-structural to the layered honeycomb materials Na2IrO3 (Ref. [11]) and â-Li2IrO3 (Ref. [32]). From neutron powder diffraction data, we present evidence of a magnetic propagation vector k ≃ (0,1,0,5), consistent with zigzag or stripy long-range magnetic ordering. We find that the calculated magnetic diffraction pattern expected for the stripy model is inconsistent with the experimental data and conclude that the zigzag model with antiferromagnetic stacking gives the best account of the true magnetic structure. Furthermore, we characterize the stability of the zigzag order in applied magnetic field and construct a magnetic phase diagram for field applied in the honeycomb layers. To complement the x-ray diffraction studies, we report electronic band-structure calculations to check the stability of the crystal structure and determine the resulting magnetic ground state of the Ruâ+ ions.

The paper is organized as follows: Section II presents the methods employed. Single-crystal diffraction results are given in Sec. III, with the space-group determination and stacking faults analysis presented in Sec. III A, the structural refinement discussed in Sec. III B, and comparison to other structural models drawn in Sec. III C. Following this, in Sec. IV we focus on the magnetic order at low temperatures through discussion of susceptibility, pulsed-field magnetization, and neutron powder diffraction results. In Sec. IV C we discuss the implications of the monoclinic symmetry for the low-energy spin excitations and in Sec. V we present results of ab initio electronic-structure calculations. Finally, conclusions are summarized in Sec. VI.

II. METHODS

Crystals of â-RuCl3 were grown by vacuum sublimation from commercial RuCl3 powder (Sigma Aldrich, Ru content 45%–55%) sealed in a quartz ampoule and placed in a three-zone furnace with the end temperatures 650 °C and 450 °C. Those temperatures were chosen in order to obtain phase-pure â-RuCl3 (the ß polytype transforms irreversibly into the â phase above 395 °C [24]) and to ensure that the Cl2 gas pressure in the ampoule did not exceed atmospheric pressure. The grown polycrystalline samples contained many flat-plate crystal pieces, often with a hexagonal shape and up to 1 mm in diameter. Single-crystal x-ray diffraction in the range 80–300 K (under N2 gas flow) was performed on many of those crystal platelets using a Mo-source Oxford Diffraction Supernova diffractometer.

Magnetometry measurements were made under static fields using both a Quantum Design Magnetic Properties Measurement System (MPMS) and vibrating sample magnetometer (VSM). Pulsed-field magnetization experiments were performed on a stack of aligned crystal platelets in both H \perp e* (field in the honeycomb layers) and H \parallel e* (field normal to the honeycomb layers) geometries. We employed an improved version of the setup described in Ref. [33], placed within a 3He cryostat with a base temperature of 0.4 K and the 60 T short-pulse magnet at NHMFL Los Alamos [34]. The magnetization values measured in the pulsed-field experiments
were calibrated against VSM data collected on the same sample.

Neutron powder diffraction measurements to obtain information about the magnetic structure were performed using the time-of-flight diffractometer WISH at the ISIS Facility in the UK. Approximately 5 g of powder \( \alpha \)-RuCl\(_3\) (extracted from the crystal growth ampoule described above) was placed in an aluminium can and mounted in a standard helium-4 cryostat with a base temperature of 2 K. Additional measurements were performed using a closed-cycle refrigerator with a base temperature of 6 K.

The electronic-structure calculations were performed with the all-electron full potential WIEN2K code \[35\]. We set the basis-size controlling parameter \( RK_{\text{max}} \) equal to 8 and considered a mesh of \( 8 \times 6 \times 8 \) \( k \) points in the first Brillouin zone (FBZ) for the self-consistency cycle. The density of states were calculated with \( 12 \times 12 \times 12 \) \( k \) points in the FBZ. All calculations were double-checked with the full potential local orbital (FPLO) code \[36\].

III. CRYSTAL STRUCTURE

A. Space group and stacking faults

The x-ray diffraction pattern was measured for many crystal platelets extracted from several growth batches. In all samples studied (over 50), one could invariably observe sharp reflections and weak diffuse scattering in rods along the direction normal to the crystal plates, as characteristic of a layered crystal structure with stacking faults \[37\]. The positions of the sharp Bragg reflections could be consistently indexed by a monoclinic unit cell with space group \( C2/m \) both at room temperature and the lowest temperature measured (80 K) with lattice parameters given in Table \( \text{I} \). Some samples were found to have a single structural domain, some were found to contain two monoclinic crystals rotated by \( \approx 120^\circ \) about the direction normal to the plates (c\*) and, other samples contained multiple structural domains. For the untwinned crystals, the diffraction patterns had the empirical selection rule for observed Bragg peaks \( h + k = \text{even} \), as characteristic of C-centering in the ab plane, and the peak intensities were symmetric under a twofold rotation around the \( b^* \) and mirror-plane reflection normal to \( b^* \), as expected for a \( 2/m \) Laue class. The highest symmetry space group consistent with the above information is \( C2/m \).

Representative data at 300 K from an untwinned crystal (of \( \approx 80 \) \( \mu \)m diameter) are shown in Figs. 1(d)–1(f), for various diffraction planes. Note that all sharp Bragg peaks are in good agreement with calculations [Figs. 1(g)–1(i)] for a \( C2/m \) structure. In addition to sharp Bragg peaks, rods of diffuse scattering are also clearly visible along \( l \) [see Figs. 1(e)–1(f)], with the general selection rule \( k = 3n + 1 \) or \( 3n + 2 \) (n integer) and \( h + k = \text{even} \) (due to C-centering). Diffuse scattering with the same selection rule was also observed in \( \text{Na}_2\text{IrO}_3 \) and attributed to faults in the stacking sequence of honeycomb \( \text{Na}_1/2\text{IrO}_3 \) layers \[11\]. By analogy, we attribute the above diffuse scattering observed in \( \alpha \)-RuCl\(_3\) as originating from occasional shifts in the ab plane by \( \pm b/3 \) between stacked RuCl\(_3\) honeycomb layers. The intensities of the sharp Bragg peaks located at integer \( l \) positions on those diffuse scattering rods are expected to have a reduced intensity compared to a fully ordered structure due to some transfer of intensity into the diffuse rod \[37\]. For the quantitative structural refinement we will show that it is helpful to distinguish between different families of Bragg peaks, and for this purpose we label the above family of Bragg peaks whose intensities are affected by diffuse scattering from sliding stacking faults as in \( \text{Na}_2\text{IrO}_3 \), as “SFa” (peaks affected by stacking faults of type “a” to distinguish them from another family of type “b,” to be discussed below).

Upon cooling to low temperatures (80 K) no new diffraction peaks appear, but a second family of diffuse scattering rods becomes apparent. This is most clearly seen by comparing Figs. 1(a) and 1(d), note the diffuse scattering rod near (2,0,−2) [Fig. 1(a), labeled peak position], which is prominent at low temperature, but only just visible at 300 K [Fig. 1(d)]. Note also in Fig. 1(c) the strong diffuse scattering along (1,±2,1) positions, almost absent at 300 K [Fig. 1(f)]. This type of diffuse scattering was not detected at 300 K in \( \text{Na}_2\text{IrO}_3 \) (Ref. [11]) and has a different selection rule \( k = 3n \) and \( h = 3m + 1 \) or \( 3m + 2 \) with \( m, n \) integers and \( h + k = \text{even} \) compared to the diffuse scattering of type “a” discussed previously. At 80 K, both families of diffuse scattering rods have comparable intensities [see Fig. 1(c)]. As before, the Bragg peaks located at integer \( l \) positions on this second family of diffuse scattering rods are expected to be reduced in intensity.

Fit to NSF peaks

[Criterion for observed reflections: \( I > 3.0\sigma(I) \)]

No. observed reflections: 32

No. fitted parameters: 3
FIG. 1. (Color online) Observed x-ray diffraction patterns (log intensity scale) for an untwinned crystal of \( \alpha \)-RuCl\(_3\) at 80 K (a)–(c), 300 K (d)–(f), shown for three different planes, compared with calculations (g)–(i) for the monoclinic \( C2/m \) structural model (Fig. 2) and the trigonal \( P3112 \) model (j)–(l). All wave vectors are labeled in r.l.u. units of the monoclinic cell and \( a^* \), \( b^* \), and \( c^* \) denote reciprocal lattice vectors of the hexagonal primitive cell of the trigonal structure (for the relation between the hexagonal and monoclinic axes, see Sec. III C). Note the sharp peaks in the data are in good agreement with the monoclinic model [compare (d)–(f) with (g)–(i)], whereas the “supercell” peaks expected in the case of the trigonal model (k)–(l) at fractional positions \( l = n + 1/3 \), \( n + 2/3 \) (integer) are clearly absent from the data, instead only diffuse scattering is found in those places.

compared to a fully ordered structure. We label this family of Bragg peaks as “SFb” (peaks affected by stacking faults of type “b”).

Finally, a third family of Bragg peaks exist that are sharp at all temperatures measured, such as (00\( n \)) (\( n \) integer) in Fig. 1(a), so appear not to be affected by the presence of stacking faults. These have the general reflection condition \( h = 3n \) and \( k = 3n \) (\( n, m \) integers and \( h + k = \) even), and we label them NSF (peaks not affected by stacking faults).

**B. Structural refinement at 80 K**

To obtain a reference, fully ordered 3D structure with no stacking faults we must refine a structural model against only those diffraction peaks that are unaffected by the presence of stacking faults. These are the family labeled NSF, as defined above. In the following, we focus primarily on the data collected at 80 K. Out of a total 1451 Bragg peaks measured, 135 are NSF peaks, of those just 32 are symmetry inequivalent after data reduction in space group \( C2/m \). Despite the small number of reflections, a full refinement using FULLPROF [38] of a structural model, with starting atomic positions for Ru and Cl taken to be those of Ir and O in the structure of Na\(_2\)IrO\(_3\), converged well. Hence, the data were found to be fully consistent with the same structural motif as that found in Na\(_2\)IrO\(_3\) with honeycomb layers of edge-sharing RuCl\(_6\) octahedra stacked vertically with an in-plane offset (see Fig. 2), with Ru in place of Ir, Cl in place of O, and removing Na altogether. However, detailed tests showed that the refinement was in fact not sufficiently sensitive to the
y position of the Ru ion, or the precise distortions of the Cl$_6$ octahedra, so the internal atomic fractional coordinates could not be uniquely determined from the X-ray data alone. The atomic positions are key to understanding the underlying physics as the exchange interactions (and their anisotropy) are expected to be strongly dependent on the geometry of the Ru-Cl-Ru bonds. So to construct a robust structural model we use ab initio density functional theory (DFT) calculations to predict the atomic positions that give the lowest-energy ground state using as input the experimentally determined space group and lattice parameters, and then check consistency of this constrained structural model with the intensities in the X-ray diffraction data. For the DFT structural relaxation calculations we employed the projector augmented wave method as implemented in the VASP package with the generalized gradient approximation (GGA) [40], as well as the full potential local orbital (FPLO) method [36].

The atomic fractional coordinates predicted by DFT within the above empirical constraints are given in Table I. The refinement of the structural model against the 80 K NSF peak intensities was repeated with atomic fractional parameters and a global scale factor left free to vary. A reliability factor of $R_{F2} = 4.2\%$ was obtained, which compared to a value of $R_{F2} = 3.7\%$ achieved for the completely free refinement (when atomic coordinates were also allowed to vary), demonstrates that the theoretically predicted atomic coordinates are fully consistent with the X-ray diffraction data. Figure 3 shows the observed structure factors squared $|F|^2$ for all families of diffraction peaks compared to those calculated from the fit against only the NSF peaks. The excellent agreement with the NSF peak intensities at 80 K is clear [Fig. 3(b), black symbols]. Furthermore, one can see that intensities of both SFa (blue) and SFb (red) peaks are systematically overestimated, consistent with the expectation that some of their nominal intensity has been transferred into the diffuse scattering in their vicinity. Figure 3(a) shows the same fit, but performed against the room-temperature data set [with empirically determined lattice parameters $a = 5.9856(4) \text{ Å}$, $b = 10.3557(5) \text{ Å}$, $c = 6.0491(4) \text{ Å}$, $\beta = 108.828(7)^\circ$ and assuming atomic fractional coordinates fixed to the DFT predicted values listed in Table I].

Even at this temperature, the structural model agrees well with the X-ray data ($R_{F2} = 5.5\%$ for NSF peaks), and the intensities of the SFb peaks (red symbols) appear to be also almost quantitatively reproduced by the model, as at this temperature the diffuse scattering near SFb peaks is almost absent, so the intensity of SFb peaks is expected to be only very weakly reduced compared to a perfectly ordered structure.

The obtained crystal structure allows us to naturally understand the strong periodic modulations in the intensity of X-ray diffraction peaks, in particular the rather conspicuous period-4 repeat in the intensity of peaks along $l$ in the $(h0l)$ plane [see Fig. 1(d)] with almost extinct peaks at $(0,0,\pm 2)$ and $(\pm 2,0,0)$ positions. The near absence of intensity at those positions is due to an almost total cancellation of the scattering from the Ru ion with that from the three Cl ions with atomic scattering factors are given in ratio almost 3 : 1. In detail, the Ru ion is located at $z = 0$, whereas the Cl ions are at $z \simeq \frac{1}{3}$ and $\frac{2}{3}$ (see Table I), so the structure factors for $(00l)$ reflections follow (to a good approximation) a period-4 sequence of values $f_{R_u} : f_{C_l} = 44 : 17 \approx 3 : 1$. Similarly, one can show that a period-4 modulation in intensity along $l$ occurs in general for $(h0l)$ peaks, with zeros at $h + l = 4n + 2$ (an integer and $h$ even) explaining all the near extinctions and apparent intensity modulations seen in Fig. 1(d). We note that such near extinctions do not occur in the diffraction pattern of the isostructural Na$_2$IrO$_3$, as the scattering factors of Ir and O are much more anisotropic (ratio almost 10 : 1) and Na is also contributing to the diffraction peak intensities.
To summarize, the x-ray diffraction patterns uniquely identify the monoclinic $C2/m$ space group both at room temperature and the lowest temperature measured (80 K), and quantitative structural refinement using fixed atomic fractional coordinates predicted by DFT, performed only against the sharp diffraction peaks whose intensity is not affected by the presence of stacking faults, gives a very good description of the data. The corresponding crystal structure is shown in Fig. 2 and consists of monoclinically stacked RuCl$_3$ honeycomb layers as in AlCl$_3$ (Ref. [31]) and Na$_2$IrO$_3$. The real materials are understood to have occasional stacking faults with respect to this reference monoclinic structure.

C. Other structural models

The current structural model assumed for $\alpha$-RuCl$_3$ (trigonal space group $P3_112$ [27], conventionally described in a hexagonal unit cell) differs from the monoclinic $C2/m$ structure primarily in the stacking sequence of the honeycomb layers, with a three-layer stacking periodicity as opposed to single layer in $C2/m$. We note that the dimensions of the unit cell are, in general, an insufficiently robust criterion to reliably distinguish between those two structural models as the monoclinic unit-cell metric is in fact very close to hexagonal, i.e., $b \simeq \sqrt{3}a$ to within better than 0.2%, and $3c \times \cos \beta \simeq -a$ to within 2%. When the latter equation is satisfied exactly, one has eclipsed (straight-on-top) stacking at the third honeycomb layer, so an alternative hexagonal cell with a three-layer periodicity along the direction normal to the layers could in principle provide an approximate metric to index the positions of Bragg diffraction peaks. In this case, the transformation between the hexagonal (subscript $h$) and symmetrized monoclinic unit-cell vectors (subscript $m$) is given by $a_m = -a_h - b_h$, $b_m = a_h - b_h$, $c_m = (a_h + b_h + c_h)/3$, where $a_m = ah$, $b_m = \sqrt{3}ah$, $\beta = \pi/2 + \text{atan}(ah/c_h)$, and $c_m = c_h/(3 \sin \beta)$.

However, the internal atomic arrangement in the monoclinic and trigonal structures is different due to the distinct symmetries of the corresponding space groups, and these differences would be directly observed in the measured single-crystal diffraction patterns. In particular, the two structures have a distinct stacking sequence of the honeycomb layers: for two adjacent layers both the symmetrized monoclinic and trigonal structures would appear identical, but for every subsequent layer in the trigonal structure the direction of the in-plane offset (defined by the monoclinic angle $\beta$) would rotate by 120° around the direction normal to the layers. The resulting three-layer stacking periodicity in the trigonal structure would lead to the appearance of extra supercell peaks along the $c^*$ axis, which, in the monoclinic basis, would occur at noninteger positions $l = n + \frac{1}{2}$ and $n + \frac{3}{4}$ ($k = 3m + 1$ or $3m + 2$, and $h + k = even$ with $h, m, n$ integers) in addition to, and with the same intensity, as the nominal peaks at integer $l = n$ positions [see Figs. 1(k) and 1(l)]. The absence of supercell peaks in our diffraction data [compare Figs. 1(e) and 1(f) with 1(k) and 1(l)] conclusively rules out the proposed $P3_112$ model. For completeness, we note that an alternative rhombohedral stacking sequence of the honeycomb layers with space group $R3$ proposed [19] for $\alpha$-RuCl$_3$ by analogy with the low-temperature phase of CrCl$_3$ (Ref. [41]) also has a three-layer stacking periodicity so would also predict supercell peaks at noninteger $l = n + \frac{1}{2}$ and $n + \frac{3}{4}$ positions, not observed in the data, so this rhombohedral structure can similarly be ruled out for the crystals studied here.

We note that if a sample contained three monoclinic twins of equal weight and rotated by 120° around $c^*$, then there would be no striking qualitative difference between the diffraction pattern from monoclinic and trigonal/rhombohedral structural models. Furthermore, under the symmetry constraints of those candidate structures there would be only slight variations in intensity due to differences in the displacements of the Cl or Ru ions from their idealized positions, which are expected to be small and likely below the experimental sensitivity. As such, measuring unwinned crystals has proved to be crucial in this study to qualitatively, and quantitatively, determine the correct monoclinic reference structure for the samples reported here.

IV. MAGNETIC PROPERTIES

A. Susceptibility and magnetization

The magnetic susceptibility of a stack of single crystals representative of those used in our structural study (Sec. III), and a 12.8 mg powder, was measured on heating (after zero-field cooling) from 2 K up to 300 K. Only a single anomaly was observed for both samples near 13 K [see Fig. 4(a)], which is indicative of long-range antiferromagnetic ordering of the ruthenium magnetic moments. Our powder data are fully consistent (in absolute units) with data previously

![FIG. 4. (Color online) (a) Magnetic susceptibility as a function of temperature for a stack of single crystals (red circles, $H \perp c^*$) representative of those used in the x-ray diffraction experiments described in Sec. III, and the powder sample used in the neutron diffraction experiments discussed in Sec. IVB (black triangles), in a magnetic field $H = 1000 \text{ Oe}$. (b) Temperature dependence of the integrated intensity of the two magnetic reflections observed in neutron powder diffraction pattern in Fig. 7, normalized to an average of unity at low temperatures. The dashed line is a guide to the eye.](image-url)
Hysteresis). For limit of experimental sensitivity (i.e., there was little or no portions of the field pulse were indistinguishable within the of the field pulses; sweeps up to 15 T at various constant temperatures. Here, to the contrary, we find order associated with a single transition, respectively or alternatively to a single phase that supports an unexpected magnetic ground state [17]. Here, to the contrary, we find that the low-field magnetic susceptibility of single crystals is consistent with that of the powder, both displaying a single transition to magnetic order at low temperatures.

Pulsed-magnetic-field data shown in Fig. 5(b) for H,T values that are a factor 5–6 times smaller than those reported on powder α-RuCl₃ samples [25]. Previous single-crystal studies have reported two magnetic transitions near 8 and 14 K (Refs. [17,19,20]), which have been attributed to either a mixture of two coherent stacking orders, with each order associated with a single transition, respectively [18], or alternatively to a single phase that supports an unexpected magnetic ground state [17]. Here, to the contrary, we find that the low-field magnetic susceptibility of single crystals is consistent with that of the powder, both displaying a single transition to magnetic order at low temperatures.

Pulsed-magnetic-field M(H,T) data are shown for field sweeps up to 15 T at various constant temperatures T in Fig. 5(b). The data shown were recorded during the rising part of the field pulses: M(H) curves from the rising and falling portions of the field pulse were indistinguishable within the limit of experimental sensitivity (i.e., there was little or no hysteresis). For H ⊥ c* the low-temperature M(H) curves show a pronounced steepening at about 8 T, characteristic of a field-induced phase transition, which gradually shifts down in field and fades as the temperature increases. This trend is more clearly seen in the full phase diagram shown in Fig. 5(a), which displays maximum values (solid symbols) of the differential susceptibility (dM/dH) as a function of H and T. The inset to Fig. 5(a) shows complementary M(H,T) data recorded in the VSM as temperature sweeps in fixed field. The same transition is seen as a peak in M(H,T) that disappears at fields above 8 T. This trend is also drawn in the main panel of Fig. 5(a), which completes a continuous phase boundary (dashed line) consistent with a single enclosed antiferromagnetic phase for α-RuCl₃ at low temperatures and modest magnetic fields applied in the honeycomb layers.

The pulsed-field data shown in Fig. 5(b) for H || c* exhibit M(H,T) values that are a factor 5–6 times smaller than those recorded on the same sample under comparable conditions for H ⊥ c*. This is likely to be due to Ru g-factor anisotropy [19]. Note that there is no sign of the phase transition observed in the other field orientation, leading us to conclude that it is a feature observed only when the field lies in the honeycomb plane.

Having measured the magnetization along the two nonequivalent directions on the same sample enables us to reliably put both data sets in absolute units by calibration against the susceptibility data measured on a powder sample [Fig. 4(a) black symbols] under the same conditions of applied field and temperature, thus avoiding the inherent uncertainties associated with measuring the precise mass of very small (of order ~0.1 mg) crystals. The powder susceptibility is expected to reflect the spherically averaged value, obtained as χ_{powders} = (2/3)χ∥ + (1/3)χ⊥ = χ⊥(2 + r)/3, where r = χ⊥/χ∥ is the susceptibility anisotropy. The single-crystal data sets in Figs. 4(a) (red symbols) and 5(b) and 5(c) were then scaled to satisfy the above relations with the powder susceptibility data at μ₀H = 0.1 T and 15 K, where the susceptibility anisotropy under those conditions was obtained as r = 0.157 from the pulsed field data.

Figure 5(c) shows M(H,T) data recorded in 60 T pulsed-field shots; as is the case with the lower-field data, there is little or no hysteresis between up and down sweeps of the field and, so, for clarity, only data recorded on the rising part of the field pulse are shown. The M(H) anisotropy persists to high fields, although the data for H ⊥ c* show signs of the approach to saturation. There are no further phase transitions visible up to 60 T in either field direction.

The shape of the magnetization curve at high field as observed by the upper traces in Fig. 5(c) with a gradually decreasing differential susceptibility upon increasing field suggests an asymptotic approach to magnetization saturation. Such a behavior of the magnetization near saturation is

![Magnetic phase diagram for single-crystal α-RuCl₃ in magnetic field H ⊥ c*.](image-url)
commonly seen [42,43] when the spin Hamiltonian does not have rotational symmetry around the applied field direction. In this case, the total spin along the field direction $\mathbf{s}_i^z = \sum \mathbf{s}_i^z$ is not a good quantum number (the operator does not commute with the spin Hamiltonian $[\mathbf{s}_i^z, \mathcal{H}] \neq 0$, where $\xi$ denotes the direction of the applied field $\mathbf{H}$ and $i$ runs through all the magnetic sites) and as a consequence even in the limit of very high fields quantum fluctuations are still present and reduce the magnetization from its fully available value, with saturation strictly reached only in the asymptotic limit of infinite field. This is qualitatively different from the case when the spin Hamiltonian does have rotational symmetry around the field direction, for example, the case of purely Heisenberg interactions $\mathcal{H} = \sum_{ij} J_{ij} \mathbf{s}_i \cdot \mathbf{s}_j$. In this case, the total spin along the field direction is a good quantum number, magnetization saturation is an exact plateau phase where quantum fluctuations are entirely absent, and the approach to magnetization saturation from below is via a sharp phase transition at a critical field $H_C$, with the susceptibility in general increasing upon increasing field up to $H_C$, then being strictly zero above it. The observed shape of the magnetization curve at high field [upper traces in Fig. 5(c)] is consistent with the former scenario with an asymptotic approach to saturation and could be taken as evidence for the presence of strongly anisotropic, non-Heisenberg exchanges in $\alpha$-RuCl$_3$, of Kitaev [43] or another strongly anisotropic form.

### B. Magnetic neutron powder diffraction

Neutron powder diffraction data were collected deep in the ordered phase (6 K) and in the paramagnetic region (20 K) with high counting statistics to allow a quantitative refinement. Additional data to monitor the temperature dependence and extract an order parameter were collected with lower statistics with high counting statistics to allow a quantitative refinement. The ordered phase (6 K) and in the paramagnetic region (20 K) reduces the magnetization from its fully available value, with very high fields quantum fluctuations are still present and reduce the magnetization from its fully available value, with saturation strictly reached only in the asymptotic limit of infinite field. The observed shape of the magnetization curve at high field [upper traces in Fig. 5(c)] is consistent with the former scenario with an asymptotic approach to saturation and could be taken as evidence for the presence of strongly anisotropic, non-Heisenberg exchanges in $\alpha$-RuCl$_3$, of Kitaev [43] or another strongly anisotropic form.

The magnetic moments of the zigzag structure are directed along the $(1,0,0)$ direction (the unique twofold axis of the crystal structure) or in the $ac$ plane. If the transition from paramagnetic to magnetic order is continuous, then the magnetic structure would be expected to adopt just one of those two configurations, which can be directly tested by the magnetic diffraction data. For parallel alignment within each pair, the resulting magnetic structure is a "striped" antiferromagnet with spins forming ferromagnetic stripes (ladders) along the $a$ axis. In the case of antiparallel alignment within each pair, the magnetic structure consists in "zigzag" ferromagnetic chains along the $a$ axis [38] for the propagation vector $\mathbf{k}$, gives magnetic basis vectors containing moments aligned along the $b$ axis (the unique twofold axis of the crystal structure) or in the $ac$ plane. If the transition from paramagnetic to magnetic order is continuous, then the magnetic structure would be expected to adopt just one of those two configurations, which can be directly tested by the magnetic diffraction data.

The two magnetic reflections observed in the difference diffraction data in Fig. 7 at $d = 3.88$ and 7.67 Å are indexed as $(−1,2,0.5)$ and $(0,1,0.5)$, respectively. The peak at higher $d$ spacing was found to be significantly broader than that at 3.88 Å. We assign this broadening to the effects of stacking faults, as discussed above. Without a fully quantitative model of the stacking faults we cannot rule out the possible existence of otherwise unobserved weak magnetic reflections close to background levels. However, all statistically significant reflections can be fit using a peak specific broadening model, hence allowing for the zigzag and stripy models, and the moment direction, to be tested.

The solid and dashed lines in Fig. 7 show the calculated diffraction patterns for both magnetic structures. In both cases, the relative intensity of the two observed reflections could only be reproduced with magnetic moments oriented within the $ac$ plane, however, within experimental uncertainties the fit to the data was not sufficiently sensitive to the precise moment direction in this plane. Furthermore, one can immediately...
To estimate the ordered Ru magnetic moment magnitude, we calibrate the magnetic diffraction intensities against the (001) nuclear reflection (Fig. 7 inset), which is unaffected by stacking faults (see Sec. III), and fit the Ru moment magnitude within the monoclinic structure (black line in Fig. 7). In the fit to the reference (001) structural peak only an intensity scale factor was varied with all the internal crystal structure parameters kept fixed to the values at 80 K (Table I), only adjusting for the effect of the lower temperature in the neutron measurements by a slight reduction in the lattice parameters, estimated by fitting the nuclear peak positions observed in the neutron diffraction data at low d-spacing (not shown). Using this procedure, we find the lower limit for the magnetic moment to be 0.64(4)µB, with the actual value being dependent on the precise moment direction, which the present data only constrain to be in the ac plane. Despite not knowing the exact moment direction, the symmetry of the ground-state magnetic structure is now well established as zigzag in-plane order with antiferromagnetic stacking along c, in qualitative agreement with previous studies [17,18]. In monoclinic symmetry, the magnetic structure is described by the magnetic super-space group Cc2/m, with basis transformation [(1,0,2),[0,1,0],[0,0,−1]] and origin shift (−1/2,0,−1/2) with respect to the parent Cc2/m unit cell.

C. Implications of monoclinic symmetry for the magnetic exchange interactions

Here, we discuss possible implications of the monoclinic crystal structure for the low-energy spin excitations in the magnetically ordered phase. Recent inelastic powder neutron scattering measurements have reported [18] dispersive magnetic excitations above a gap of ≈1.7 meV and it was proposed that features observed in the inelastic spectrum at intermediate energies above this gap could be understood based on a minimal Kitaev-Heisenberg model on the honeycomb lattice, with an antiferromagnetic Kitaev exchange K and a ferromagnetic Heisenberg term J. However, it was pointed out that this minimal model could not account for the observed spin gap, as for a honeycomb lattice with full threefold symmetry (as expected in the trigonal P3112 structural model) the exchanges along the three bonds meeting at each lattice site are symmetry equivalent, and in this case linear spin-wave theory predicts a gapless spectrum [18], contrary to that observed experimentally. We note that the Cc2/m monoclinic structure breaks the symmetry between the three bonds in the honeycomb planes, making the b-axis bond nonequivalent to the other two bonds, which remain symmetry equivalent; this opens the possibility that the magnitude of the anisotropic exchange could be different between the two families of bonds. By repeating the linear spin-wave calculations reported in Ref. [18], we find that an anisotropy of order 10% in the magnitude of the Kitaev term between the two families of bonds (larger in magnitude for the b-axis bond) would be sufficient to account for the magnitude of the observed spin gap, suggesting that nonequivalence between the different bonds in the honeycomb plane induced by the underlying monoclinic distortions may provide a natural mechanism to explain the observed spin gap.

V. ELECTRONIC STRUCTURE

Here, we discuss the implications of the monoclinic crystal structure for the electronic band structure and the magnetic ground state of the Ru ions. Within a honeycomb layer, the difference in the atomic positions in the trigonal P3112 [27] compared to the monoclinic Cc2/m models is on visual inspection minimal. However, subtleties of the crystal structure in fact have profound implications for the nature of the electronic structure. The trigonal crystal structure features shorter Ru-Ru bonds, and as a result the calculated electronic structure is dominated by Ru-Ru direct hopping. On the other hand, in the present monoclinic structure the dominant hopping process is one via Cl p states, which, as discussed in Refs. [44–46] for Na2IrO3, leads to the formation of quasimolecular orbitals (QMO) that consist of a linear combination of t2g states of the six Ru atoms in a hexagon.

In Fig. 8, we show the nonrelativistic density of states within GGA projected onto the QMO basis for α-RuCl3 in the Cc2/m and P3112 crystal structures, as well as that for Na2IrO3 for comparison. While α-RuCl3 (Cc2/m) and Na2IrO3 are predominantly diagonal in the QMO basis, this is not the case for α-RuCl3 (P3112) as can be observed from the strong mixing of QMO states.

To analyze spin orbit and correlation effects, we present in Fig. 9 the electronic structure of α-RuCl3 (Cc2/m) in the GGA, GGA + SO (GGA plus inclusion of spin-orbit effects), and GGA + SO + U (GGA plus inclusion of spin-orbit effects and onsite Coulomb repulsion U) approximations as implemented in WIEN2k [35]. Here, an insightful comparison with Na2IrO3 [44,45], the combination...
of accidental degeneracy of the two highest QMOs, \(A_{1g}\) and \(E_{2g}\), combined with strong spin-orbit coupling, largely destroys the QMO and leads instead to the formation of relativistic \(j_{\text{eff}} = \frac{1}{2}\) orbitals (the QMOs are still relevant as they generate unexpectedly large second- and third-neighbor magnetic interactions \([11,14]\)). Adding the Hubbard \(U\) in Na\(_2\)IrO\(_3\) increases the band gap, but does not affect the electronic structure in any qualitative way. However, given that the spin-orbit coupling on Ru is much smaller than on Ir, turning on the spin-orbit coupling leaves the QMO picture in \(\alpha\)-RuCl\(_3\) \((C2/m)\) almost intact \([Fig. 9(b)]\). Interestingly, adding \(U\) dramatically changes the electronic structure \([Fig. 9(c)]\). Such an addition effectively renormalizes the one-electron hopping by a factor of \(t/\alpha\) and increases the effect of spin-orbit coupling that now becomes an important player. Eventually, the electronic structure with both spin orbit and \(U\) looks surprisingly similar to that of Na\(_2\)IrO\(_3\) \((\alpha\)-RuCl\(_3\) \((C2/m)\) the much stronger correlation conspires with spin orbit, which otherwise is too weak to overcome the one-electron hopping effects.

The GGA + SO + \(U\) band structure for \(\alpha\)-RuCl\(_3\) \((C2/m)\) can be projected onto the \(j_{\text{eff}} = \frac{1}{2}\) basis as shown in the density of states in Fig. 9(c). While there is some mixing between the two projections, \(j_{\text{eff}} = \frac{1}{2}\) has the dominant contribution at the Fermi level. Therefore, a description of this system in terms of \(j_{\text{eff}} = \frac{1}{2}\) orbitals may still be valid. This is in qualitative agreement with GGA + SO + \(U\) calculations reported for \(\alpha\)-RuCl\(_3\) in the \(P3_112\) structure \([16]\), although the two electronic structures differ quantitatively.

VI. CONCLUSIONS

We have proposed a revised three-dimensional crystal structure for the layered honeycomb magnet \(\alpha\)-RuCl\(_3\) based on x-ray diffraction on untwinned crystals combined with \textit{ab initio} structural relaxation calculations. In contrast with the currently assumed three-layer stacking periodicity, we have found a single-layer stacking periodicity with a monoclinic unit cell, isostructural to Na\(_2\)IrO\(_3\), with occasional faults in the stacking sequence. In powder neutron diffraction and in susceptibility measurements on both powders and single crystals we have observed a single magnetic transition near 13 K, and through analysis of the magnetic diffraction pattern we have confirmed that this phase has zigzag antiferromagnetic order. Using both static and pulsed magnetic field experiments, we have observed that the zigzag phase is suppressed by relatively small magnetic fields (\(\approx 8\) T) applied in the honeycomb layers, whereas it is robust in fields applied perpendicular to the honeycomb layers. We have discussed how the monoclinic crystal structure could provide a natural mechanism to explain the spin gap observed in inelastic neutron scattering experiments and how the asymptotic shape of the magnetization curve at high fields near saturation is consistent with proposals for strongly anisotropic (non-Heisenberg) magnetic interactions.
